Running title: GLA p.E66Q mutation and high risk of stroke

Key words: Fabry disease, α-galactosidase A, GLA, cerebral small-vessel occlusion, lacunar infarction, cerebral infarction, cerebral hemorrhage, risk factors
Abstract

Background and purpose: GLA is the causative gene of Fabry disease, an X-linked lysosomal storage disorder resulting from α-galactosidase A (α-GAL) deficiency. Stroke is an important manifestation of Fabry disease, and recent epidemiological studies indicated that up to 4.9% of young male cryptogenic stroke patients have GLA mutations. To determine the importance of GLA mutations in the general stroke population, we measured the frequency of GLA mutations in Japanese male ischemic stroke patients with various risk factors and ages.

Methods: A total of 475 male ischemic stroke patients (average age 69.7±12.5 years), were enrolled in this study. A blood sample was obtained to produce blood spots for measurement of α-GAL activity. Blood samples with decreased enzymatic activity were reassayed and the entire GLA gene was analyzed by direct DNA sequencing if α-Gal A activity was consistently low.

Results: α-Gal A activity was decreased in 10 men, 5 of whom (1.1%) had the GLA gene mutation, p.E66Q. All ischemic stroke patients with p.E66Q mutation had substantial residual α-Gal A activity, in contrast to patients with classic-type Fabry disease. Clinically, all patients with p.E66Q mutation were > 50 years old and had multiple small-vessel occlusions (lacunar infarctions). Statistical analysis using Fisher’s exact test showed the allele frequency of GLA p.E66Q in patients with small-vessel occlusion to be significantly higher than that in the general Japanese population (odds ratio 3.34, P=0.025).

**Introduction**

Fabry disease (MIM301500) is an X-linked lysosomal storage disorder resulting from deficiency of α-galactosidase A (α-Gal A) [1]. The enzymatic defect leads to progressive accumulation of globotriaosylceramide (GL-3) and related glycosphingolipids in the vascular endothelial lysosomes of the kidneys, heart, brain, and skin. Affected males who have little or no detectable α-Gal A activity exhibit the classic phenotype with onset of angiokerataoma, acroparesthesia, and hypohidrosis in childhood. With advancing age, the occurrence of renal failure, cardiac disease, and stroke lead to a decline in activities of daily living and premature death. Stroke is one of the major complications of classic Fabry disease [2] and has been described in 6.9%–24.2% of patients [3-5]. Estimates of the prevalence of classic Fabry disease vary from 1 in 40000 to 1 in 60000 [1, 6].

On the other hand, patients with substantial levels of residual α-Gal A activity have late-onset milder phenotypes, including renal [7] and cardiac [8] variants. Recent studies involving newborn screening for α-Gal A activity in Fabry disease showed surprisingly high incidences of mutations of 1 in 1250–3100 male infants [9, 10]. Most mutations found in newborn screening were associated with the late-onset variant phenotype, suggesting that many patients with these GLA mutations are underdiagnosed. Screening for Fabry disease in high risk populations identified previously undiagnosed Fabry patients in 0.2% to 1.2% of males undergoing hemodialysis [7, 11, 12] and 0.9% to 4% of males with left ventricular hypertrophy or hypertrophic cardiomyopathy [8, 13, 14]. Furthermore, the prevalence of unrecognized Fabry disease in young male patients with stroke was reported to be up to 4.9%
However, most stroke patients are elderly and there has been only one population-based study in unselected patients with stroke [21]. It is likely that GLA mutation is itself a risk factor for accelerated atherosclerosis and cardiac and renal disease, which can lead to emboli and hypertension, and therefore unrecognized Fabry patients may be found among elderly stroke patients [22]. To determine the importance of GLA mutations in the general stroke population, we measured the frequency of GLA mutations in Japanese male ischemic stroke patients with various risk factors and ages.

Methods

Patients

Fifteen clinical neurology departments in Nagano prefecture, Japan, participated in this prospective cross-sectional study. From August 2007 to December 2011, 475 male patients aged 20–91 years (mean±SD: 69.7±12.5 years), presenting consecutively at a participating neurology department with ischemic stroke, were enrolled in this study. Patients who were unable to provide informed consent or who had already been diagnosed with Fabry disease were excluded from the study. This study was approved by the Ethical Committee of Shinshu University School of Medicine and the ethics committees of each of the participating clinical neurology centers, and written informed consent was obtained from each patient prior to enrollment. After informed consent was obtained, demographic data, cerebrovascular risk factors, presence of signs and symptoms of Fabry disease, and clinical and neuroimaging data were registered in a database using case report forms. Assessment of clinical symptoms and
signs suggestive of Fabry disease was performed in all patients with GLA gene mutations.

Screening for angiokeratoma was performed by routine clinical examination, and the presence of acroparesthesia and hypohidrosis was determined by anamnesis. In addition, cardiac function tests, including serum brain natriuretic peptide (BNP) and human atrial natriuretic peptide (hANP) concentrations, chest roentgenography, electrocardiography, and echocardiography, and renal function tests, including routine urine test and determination of serum creatinine and blood urea nitrogen (BUN) levels, were performed in all patients with GLA mutation.

**α-Gal A enzyme assay and mutation analysis**

A blood sample was obtained for production of blood spots for measurement of α-Gal A activity. α-Gal A activity was determined using a fluorescent substrate as described previously [23]. Briefly, 40 μL of McIlvan buffer (0.1 M citrate, 0.2 M NaH₂PO₄, 36.8 : 63.2, pH 6.0) was added to each well of 96-microwell plates. Three millimeter punch specimens of dried blood spots were added to the buffer and processed for extraction at room temperature for 2 h. Aliquots of 30 μL of blood extract were transferred to fresh 96-microwell plate. An aliquot of 100 μL of the reaction mixture (3.5 mM 4-MU galactosylpyranoside, 100 mM citrate, 200 mM phosphate, 100 mM N-acetylglactosamine) was added to each well of the microwell plates and incubated at 37°C for 24 h. The reaction was terminated with 150 μL of termination solution (300 mM glycine, NaOH, pH 10.6) immediately after the reaction. Fluorescence intensity from the 4-methylumbelliferones in the wells was measured with a
fluorescence plate reader (BIO-TEK) at 450 nm. One unit (AgalU) of enzymatic activity was equal to 0.34 pmol of 4-methylumbelliferyl-D-galactopyranoside cleaved/h/disc. Blood samples with decreased enzymatic activity (<17 AgalU) were reassayed.

If blood αGal A activity was consistently low, the entire GLA gene was analyzed. For DNA analysis, total genomic DNA was extracted from leukocytes of patients. All 7 exons and the flanking intronic sequences of the GLA gene were amplified by polymerase chain reaction (PCR), and the amplification products were analyzed by a direct sequencing (Figure 1).

Results

Clinical data of enrolled patients

Table 1 summarizes the demographic characteristics of the enrolled patients. The mean age (±SD) in the cohort of 475 patients participating in this study was 69.7±12.5 years. Stroke etiology was classified according to the Trial of Org 10172 in Acute Stroke Treatment (TOAST) criteria [24] as large-artery atherosclerosis in 114 patients (24.0%), cardioembolism in 79 (16.6%), and small-vessel occlusion (lacunar infarction) in 240 (50.5%). Stroke of other determined etiology was present in 12 patients (2.5%): cervicocephalic arterial dissection (n=4) and paraneoplastic coagulopathy (n=8). Stroke of undermined etiology was present in 61 patients (12.8%). Subtypes of ischemic stroke overlapped in 31 patients, as they had histories of multiple ischemic strokes with different subtypes.

Diagnostic test results
The average \( \alpha \)-Gal A activity of the study population was \( 27.7 \pm 10.7 \, \text{AgalU} \). The distribution of \( \alpha \)-Gal A activity in the whole study population is shown in Figure 2. Initial screening for \( \alpha \)-Gal A activity in blood spots from 475 male patients with stroke detected 28 (5.9\%) patients with enzyme level below the normal cut-off value of 17.0 AgalU. A repeat blood spot was obtained from 20 patients. When retested, 10 (2.1\%) patients had \( \alpha \)-Gal A activities <17.0 AgalU, whereas the other 10 (2.1\%) had normal enzyme activities (\( \geq 17 \) AgalU). DNA sequencing of GLA was performed in these 10 doubly screened-positive patients with low \( \alpha \)-Gal A activity, and GLA gene mutation was identified in 5 (1.1\%) patients. All 5 patients had the same missense mutation, a single base sequence change (c.196G>C) causing substitution of a glutamate residue with glutamine at codon 66 (p.E66Q). The average \( \alpha \)-Gal A activity of the stroke patients with p.E66Q mutation was 11.3\( \pm \)1.6 AgalU (range: 9.8–13.5 AgalU), which was relatively high compared to patients with classic type Fabry disease.

Clinical data of patients with GLA p.E66Q mutation

The clinical, biochemical, and molecular features of the patients with GLA p.E66Q mutation are summarized in Table 2. All patients with p.E66Q mutation were older than 50 years with a mean age of 69.6\( \pm \)12.5 years. All patients had multiple small-vessel occlusions (Figure 3), which were accompanied by white matter lesions (leukoaraiosis) in 3 patients (Figure 3C, E, G). Intracerebral hemorrhage was observed in 4 patients. Three patients had a history of symptomatic intracerebral hemorrhage (Figure 3B) and the other patient had asymptomatic multiple microbleeds detected by T2*-weighted MRI (Figure 3F). Two patients took low
doses of aspirin when they developed cerebral hemorrhage. Vertebrobasilar dolichoectasia was observed in one patient (Figure 3D). Increased signal intensity in the pulvinar region on T1-weighted MRI was not observed in any patients. Two patients had a history of hypertension; however, their blood pressures were well controlled by antihypertensive drugs. None of the patients had other common risk factors for stroke, including dyslipidemia, diabetes mellitus, hyperuricemia, and smoking. No patients with GLA p.E66Q mutation showed characteristic symptoms of Fabry disease, such as renal dysfunction, cardiomyopathy, acroparesthesia, hypohidrosis, and angiokeratoma. None of patient with p.E66Q mutation had a family history of Fabry disease, although an uncle of patient 1 and mothers of patient 2 and 3 had histories of cerebral infarction, and a brother of patient 2 had a history of chronic renal failure (Supplementary figure 1).

**Allele frequencies of the GLA p.E66Q mutation in the Japanese population and statistical analysis**

To estimate the frequency in the general Japanese population of the GLA p.E66Q mutation found in the ischemic stroke patient cohort, we utilized the data from newborn screening for Fabry disease performed in Kumamoto prefecture from October 2009 to May 2010. In this screening, we tested 5051 consecutive male neonates (5051 alleles). This study was approved by the Kumamoto University Ethics Committee and written informed consent was obtained from each parent prior to enrollment. Genomic DNAs were isolated from whole blood, and exon 2 of the GLA gene was amplified by PCR. The amplification product was analyzed by
direct sequencing. We identified 32 hemizygous male neonates, and the allele frequency of the GLA p.E66Q in the Japanese population was thus determined to be 0.637%. Statistical analysis using the Fisher’s exact test indicated that the allele frequency of GLA p.E66Q in patients with small-vessel occlusion was significantly higher than that in the general Japanese population (odds ratio 3.34, \( P=0.025 \)) (Table 3). However, in all ischemic stroke, large-artery atherosclerosis, cardioembolism, and non-cardioembolism patients, the odds ratios were 1.67, 1.39, 0, and 2.01, respectively; the differences were not statistically significant (Table 3).

**Discussion**

Screening for Fabry disease in high-risk populations became an important concern when enzyme replacement therapy became available [25]. Studies performed in different settings indicated severe complications of Fabry disease, including left ventricular hypertrophy/hypertrophic cardiomyopathy [8, 13, 14], renal insufficiency [7, 11, 12], and stroke [15-21]. The prevalence of unrecognized Fabry disease in young male patients with stroke was first reported in 2005 [15]. Since then, several studies have estimated the prevalence of Fabry disease in young male patients with stroke as ranging from 0% to 4.9% [15-20]. Recently, Rolfs et al. [19] reported the results of the largest screening for Fabry disease in young patients with acute cerebrovascular disease. They enrolled 5023 patients from 15 European countries and found 27 patients (0.54%) with definite Fabry disease and 18 patients (0.36%) with probable Fabry disease. However, most stroke patients are elderly and there has been only one population-based study in unselected patients with stroke [21].
In the present study, 5 patients were identified as having GLA mutation and all of them had the same missense mutation, c.196G>C (p.E66Q). All patients with p.E66Q mutation showed similar clinical pictures, i.e., multiple small-vessel occlusions with a high frequency of intracerebral hemorrhage. Interestingly, most patients with this mutation lacked common risk factors for stroke. Only two patients had hypertension and their blood pressures were well controlled by antihypertensive drugs (Table 2). The p.E66Q mutation was first identified in a male patient with classic-type Fabry disease. However, he also had another GLA missense mutation, p.R112C, in the same allele, which was predicted to cause a large structural change in the α-Gal A protein that leads to classic type Fabry disease [26]. Subsequently, 26 patients with GLA p.E66Q mutation who developed adult-onset left ventricular hypertrophy or renal insufficiency were identified [7, 12, 27-29], and therefore this mutation was considered to be pathogenic, causing late-onset variant Fabry disease. However, none of these studies provided histological evidence confirming the diagnosis of Fabry disease in such cases. Recently, subjects harboring the p.E66Q mutation in the GLA gene have been found at unexpectedly high frequencies among Korean [30] and Japanese [31] populations, which has raised interest regarding whether p.E66Q is a disease-causing mutation or a functional polymorphism.

Recent studies showed that the structure of α-Gal A protein with the p.E66Q amino acid substitution was less stable than that of the wild-type protein [31], and plasma and white blood cell α-Gal A activities in male subjects harboring the p.E66Q mutation were 13%–26% and 19%–65% of the normal mean α-Gal A activity, respectively [30, 31], compatible with our dried blood spot enzymatic assay results (approximately 40% of the normal mean) (Figure
The levels of these residual α-Gal A activities of the individuals with p.E66Q mutation were almost the same as those of male stroke patients with p.R118C and p.D313Y mutations identified in a Portuguese screen (PORTYSTROKE study) [17]. GLA p.D313Y mutation was found in 0.45% of normal X chromosomes in the Caucasian population [32]. In the PORTYSTROKE study [17], the allele frequency of p.D313Y in the stroke population was higher than that in normal controls, although the difference was not statistically significant. In this study, we showed that the allele frequency of the GLA p.E66Q in patients with small-vessel occlusion was significantly higher than that in the general Japanese population (odds ratio 3.34, \( P=0.025 \)) (Table 3), indicating that this mutation confers a high risk of small-vessel occlusion in Japanese males.

In this study, the frequency of p.E66Q mutation in control subjects was determined by DNA sequencing, while that in stroke patients was determined by enzymatic screening followed by DNA sequencing. Therefore, the frequency of p.E66Q in stroke patients is likely to have been underestimated. Fuji et al. [29] analyzed the prevalence of Fabry disease in Japanese hemodialysis patients using dried blood spot screening followed by DNA sequencing, which was identical to the method used in the present study. They found only one patient with p.E66Q mutation among 625 Japanese male hemodialysis patients (prevalence of p.E66Q mutation was 0.16%), which was much lower than that in our newborn DNA screen (Table 3), suggesting that we may have missed a substantial number of patients with this mutation in dried blood spot enzymatic screening. In addition, we could not follow-up 8 patients whose α-Gal A activities were below the cutoff value at the initial screening because
they moved to other hospitals or clinics. Therefore, there may have been additional patients with GLA mutations among those who dropped out, and therefore the frequency of p.E66Q in stroke patients may have been underestimated in this study. Another point to be taken into consideration is patient selection bias, as we enrolled patients only from selected neurology departments, while a substantial number of stroke patients may be managed by neurosurgeons. In addition, we could not obtain informed consent from some of severe stroke patients. These may explain why the proportion of small-vessel occlusion was more than 50% in this study.

Although DNA sequencing of the GLA gene in all patients is necessary to determine the precise frequency of p.E66Q mutation in stroke patients, it is clear that p.E66Q mutation in the GLA gene is an important genetic risk factor for small-vessel occlusion in elderly Japanese males.

The precise pathomechanism by which GLA p.E66Q mutation increases the risk of lacunar infarction remains unknown. Recently, it was reported that cerebral small-vessel disease, which is known to be associated with lacunar infarction, white matter lesions (leukoaraiosis), and cerebral hemorrhage, rather than large-artery stroke, is frequently observed in Fabry disease [4, 5, 33, 34]. These observations are compatible with clinical findings of our patients with p.E66Q mutation who developed multiple small-vessel occlusions and cerebral hemorrhage. Our findings suggest that GLA mutations associated with relatively high residual α-Gal A activity may add to the risk of cerebral small-vessel disease, possibly by contributing to the underlying multifactorial pathogenesis rather than through a classic Mendelian effect.
Enzyme replacement therapy (ERT) is currently the only approved therapy for Fabry disease. However, patients with GLA p.E66Q are not considered to be candidates for ERT, since p.E66Q is not a causative mutation for classic-type or variant-type Fabry disease [30, 31]. On the other hand, Shimotori et al. [28] reported that 1-deoxygalactonojirimycin, an active site specific pharmacological chaperone (ASSC), significantly increased α-Gal A activity of COS-7 cells with GLA p.E66Q mutation, suggesting that ASSC may be a potential therapeutic option for patients with this mutation.

Acknowledgments

The authors thank the physicians who referred the patients for this study, including Dr. H Makishita, Dr. M. Ushiyama, Dr. K Fukushima, Dr. T Yoshinaga, Dr. K Oguchi, Dr. T Yoshida, Dr. Y Shimojima, Dr. K Machida, Dr. H Morita, Dr. K Kaneko, Dr. K Yoshida, Dr. T Hashimoto, and Dr. W Ishii.
